ABSTRACT

We evaluated whether sliding-window analysis can reveal functionally relevant brain network dynamics during a well-established fear conditioning paradigm. To this end, we tested if fMRI fluctuations in amygdala functional connectivity (FC) can be related to task-induced changes in physiological arousal and vigilance, as reflected in the skin conductance level (SCL). Thirty-two healthy individuals participated in the study. For the sliding-window analysis we used windows that were shifted by one volume at a time. Amygdala FC was calculated for each of these windows. Simultaneously acquired SCL time series were averaged over time frames that corresponded to the sliding-window FC analysis, which were subsequently regressed against the whole-brain seed-based amygdala sliding-window FC using the GLM. Surrogate time series were generated to test whether connectivity dynamics could have occurred by chance. In addition, results were contrasted against static amygdala FC and sliding-window FC of the primary visual cortex, which was chosen as a control seed, while a physio-physiological interaction (PPI) was performed as cross-validation. During periods of increased SCL, the left amygdala became more strongly coupled with the bilateral insula and anterior cingulate cortex, core areas of the salience network. The sliding-window analysis yielded a connectivity pattern that was unlikely to have occurred by chance, was spatially distinct from static amygdala FC and from sliding-window FC of the primary visual cortex, but was highly comparable to that of the PPI analysis. We conclude that sliding-window analysis can reveal functionally relevant fluctuations in connectivity in the context of an externally cued task.

Introduction

Intrinsic functional connectivity (FC) networks, obtained with fMRI, are not static but can change their configuration considerably at different time scales, ranging from seconds, minutes to hours (Allen et al., 2014; Chang and Glover, 2010; Gonzalez-Castillo et al., 2014; Handwerker et al., 2012; Hutchison et al. 2013a; Shen et al., 2015). Changes in resting-state FC observed at longer time scales can be induced by learning (e.g., Lewis et al., 2009; Schultz et al., 2012), and large state transitions such as sleep (e.g., Horowitz et al., 2009, 2008), anesthesia (e.g., Boveroux et al., 2010), or stress (e.g., Veer et al., 2011), whereas variations in intrinsic FC at the time-scales of seconds

to minutes are detectable within one scanning session (Handwerker et al., 2012; Shehzad et al., 2009; Wang et al., 2012). In contrast to conventional connectivity analysis, in which connections are typically treated as static, techniques investigating non-stationarity of FC have revealed a rich dynamic organization of resting-state networks. These networks tend to segregate and integrate into spatially and temporally overlapping subcomponents over short time intervals (Karahanoğlu and Van De Ville, 2015). For example, the default mode network (DMN), which is particularly active during resting-state, includes several functionally distinct and spatially overlapping sub-networks that exhibit their own time-dependent pattern of coupling with other networks (Smith et al., 2012). Zalesky et al. (2014) found that most

dynamic connections are intermodular, which means that these connections link brain regions from topologically separable modules. Sporadic intervals during which multiple pairs of brain regions spontaneously fluctuate in and out of high correlation over time might be an efficient mechanism of information exchange between neuronal populations (Zalesky et al., 2014), which, in turn, enables the brain to dynamically integrate and coordinate different neural systems in response to internal and external stimuli across multiple time scales (Hutchison et al., 2013a). Hence, the analysis of time-varying FC has the potential to improve our understanding of brain function. Yet, it remains unclear which techniques are the best for characterizing functionally relevant brain network dynamics with fMRI.

Due to its analytical simplicity, such as computational efficiency and interpretability, sliding-window analysis is the most commonly used strategy for examining time-dependent changes in FC during rest (Chang and Glover, 2010; Hutchison et al., 2013b). Yet, it remains debatable whether the obtained fluctuations in resting-state FC over time with the sliding-window analysis are truly non-stationary, whether these can be attributed to neuronal activity (Hutchison et al., 2013a; Preti et al., 2016), whether their statistical estimates are valid and reliable (Betzel et al., 2016; Hindriks et al., 2015; Hlinka and Hadrava, 2015; Zalesky and Breakspear, 2015), and which of its parameters, such as window size or offset, should be used to best characterize connectivity dynamics during resting-state when the timing, duration, and composition of transient FC patterns are unknown (Leonardi and Van De Ville, 2015; Shakil et al., 2016). To address some of these challenges, previous studies investigated the performance of sliding-window analysis with simulated and empirical data linked to behavioral measures or simultaneously acquired electrophysiology.

Studies that used simulated data identified statistical pitfalls in the assessment of time-varying connectivity retrieved with the sliding-window analysis and analyzed the performance of the method in characterizing FC dynamics. For example, Hindriks et al. (2015) pointed out that the mere presence of fluctuations in FC observed with the sliding-window analysis is not evidence of connectivity dynamics, and emphasized the importance to test against a null distribution of surrogate data when inferring time-varying connectivity. The method's performance strongly depends on window length, which should be large enough to permit robust estimation of FC, yet small enough to detect potentially interesting transient fluctuations in FC. Window lengths between 30–60 s seem favorable (Allen et al., 2014; Hutchison et al., 2013b; Jones et al., 2012; Liegeois et al., 2016; Shirer et al., 2012; Yang et al., 2014), but the exact duration of transiently stable FC patterns remains rather unknown and might change with task demands. Shakil et al. (2016) showed that window size and offset may have the biggest impact on the accuracy of the results, followed by such factors as noise levels and temporal filtering. In addition, the frequency components of the fMRI signal tend to interact with the size of the window, and produce spurious fluctuations of sliding-window connectivity (Leonardi and Van De Ville, 2015). Such spurious fluctuations can be avoided by first applying a high-pass filter to the original time series (i.e., before windowing) with a cut-off frequency of $1/w$, where w represents the length of the window in seconds.

For empirical data, the output of the sliding-window analysis is typically fed into a clustering algorithm to retrieve transient FC patterns, which have their specific temporal and spatial features, and which are presumed to reflect cognitive operations. With this procedure empirical research showed that intrinsic FC alternates between a finite number of transient connectivity patterns, which emerge and dissolve over short periods of time (Allen et al., 2014). Such transient FC patterns can be characterized in terms of their temporal and spatial characteristics. For example, their temporal characteristics tend to differentiate between groups (in case of schizophrenia patients, see Damaraju et al. 2014). Spatially, regions that exhibit functional diversity tend to participate in different transient FC patterns. Such

association was previously observed for the posteromedial cortex, a key region in the DMN: The subdivisions of the posteromedial cortex take on different transient FC patterns, and each subdivision has its own preferred connectivity state (Yang et al., 2014). Interestingly, the percentage of time that each of these subdivisions spend in a given FC state could be associated with behavioral performance based on executive functions. While analyses of transient FC states that occur during resting-state do provide information about intrinsic connectivity dynamics, such analyses typically assume the presence of distinct FC states. Sharp transitions between such states, however, may be less likely to occur in the brain than more gradual changes in FC dynamics.

The gradual changes can be tracked with concurrent independent measurements, such as simultaneously acquired electrophysiological (e.g., EEG) or peripheral physiological (e.g., heart rate) data. Simultaneous recordings of fMRI and EEG showed that variations in FC are to some degree of neuronal origin and perhaps linked with changes in cognitive or vigilance state (Chang et al., 2013a; Tagliazucchi et al., 2012). In a similar vein, Chang et al. (2013b) demonstrated that intrinsic amygdala sliding-window FC with the brainstem, thalamus, putamen, and dorsolateral prefrontal cortex is associated with changes in autonomic state, as indexed by temporal dynamics of heart rate variability. Yet, heart rate variability can contribute directly to the measured BOLD signal through hemodynamic and pulsatile effects (Birn, 2012; Chang et al., 2009), so it is uncertain whether measured FC dynamics reflect neural coupling or these other, potentially confounding, factors. Although these studies informed us about (neuro-)physiological contribution to fMRI connectivity dynamics revealed by sliding-window analysis, one could only speculate whether the obtained dynamics are functionally relevant. Resting-state indeed seems to reflect the functional architecture of the brain (Sadaghiani and Kleinschmidt, 2013), as it tends to maintain the connectivity dynamics induced by a behavioral context (e.g., Lewis et al., 2009; Tambini et al., 2010). Yet, it remains unclear whether sliding-window analysis is able to capture such functionally relevant connectivity dynamics. Hence, it might be crucial to first study whether sliding-window FC can be related to cognitive processing during a well-described cognitive task.

In the current study we therefore investigated whether the sliding-window analysis is able to capture cognitively relevant fluctuations in FC induced by a task. For this purpose we tested whether connectivity dynamics during a well-established classical fear conditioning paradigm, measured with a sliding-window analysis, can be associated with task-induced changes in physiological arousal and vigilance, as reflected by the skin conductance level (SCL). Simultaneous acquisition of SCL during the task enabled us to look at gradual changes in FC associated with cognitive processing that is typically involved in the acquisition of fear.

We used the amygdala as an a priori seed for the FC analysis, because it is crucial for the acquisition of conditioned fear responses, including modulation of autonomic function (Phelps and LeDoux, 2005), such as skin conductance. Fear conditioning is typically marked by the gradual increase in the skin conductance response to a neutral stimulus (the conditioned stimulus, CS) that is repetitively paired with an aversive stimulus (the unconditioned stimulus, UCS, typically an electric shock), which in turn leads to changes in the SCL over the course of the learning (Delgado et al., 2006; Phelps et al., 2004). In parallel, fear conditioning leads to changes in amygdala activation (LaBar et al., 1998), and its FC with the medial prefrontal cortex (Kim et al., 2011; Liu et al., 2011). Thus, simultaneously acquired SCL reflects changes in physiological arousal and vigilance (Boucsein, 2012), which are likely associated with changes in amygdala activity and amygdala-prefrontal coupling that occur during fear conditioning (Davis, 1992; LeDoux, 2000). We expected that sliding-window FC between the amygdala and medial prefrontal cortex would be associated with the fluctuations in SCL, which, in turn, would indicate connectivity dynamics involved in the acquisition of fear.

Methods and materials

Participants

Thirty-four healthy German volunteers were recruited in Bonn to take part in a study on fear conditioning and extinction, which comprised a two-day scanning session. Its results were previously published elsewhere (Bilkei-Gorzo et al., 2012). Two participants were excluded from the analyses: imaging data (fMRI) of one participant were unavailable, and physiological data (skin conductance level) of another participant lacked fluctuations over time. The final sample comprised thirty-two participants (15 female, mean age=26 years, SD=5.59).

None of the participants had a lifetime diagnosis or a family history of affective disorders. All participants gave written informed consent, and the study was approved by the local ethics committee of the University of Bonn.

Study design and procedure

The original study involved a task for the acquisition and extinction of fear responses that was based on a partial reinforcement learning paradigm (Phelps et al., 2004). The task led to significant activation in brain regions responsible for fear memory formation and extinction, as well as to significant changes in its physiological markers (i.e., skin conductance response), which was presented in the original report (Bilkei-Gorzo et al., 2012).

For the purpose of this study, we used the data of the fear conditioning phase only. In this phase, participants were exposed to a mildly painful laser shock to the foot and colored squares (blue and green), which played a role as aversive unconditioned stimulus (UCS) or conditioned stimuli (CS), respectively. One of the colored squares (CS+) was partly paired with the UCS, while the other one (CS-) was never paired with the UCS. Participants were exposed to the same sequence of 20 presentations each of the CS+ and CS- in a pseudo-randomized order. Ten additional CS+ presentations co-terminated with the UCS. This was a continuous task, in which every stimulus presentation lasted 4 s and an inter-stimulus interval was set to 12 s to allow the skin conductance to recover in between trials. After the acquisition phase, participants rated the intensity of the pain stimulus on a 10-point Likert scale (0—not painful at all, 10—unbearable pain). Before the start of the study participants were told that they would see blue and green colored squares, and that it might be possible that during the presentation of either the blue or the green square a painful stimulus would be applied on their left foot.

Imaging data acquisition and preprocessing

Anatomical and functional imaging data were acquired with a Phillips Achieva 3 T scanner at the Department of Radiology, University of Bonn. A standard high-resolution T1-weighted anatomical scan (1mm isotropic voxels) was acquired for registration purposes. Functional images were acquired with a T2*-weighted gradient-echo echo-planar imaging (EPI) sequence using parallel imaging (sensitivity encoding, SENSE factor 2) with the following scan parameters: 413 volumes, 39 axial slices, 3×3×2.4 mm voxels, 0.6 mm slice gap, TR=1960 ms, TE=30, flip angle=80°, FoV=192 mm (64×64 matrix).

fMRI data processing was carried out using FEAT (fMRI Expert Analysis Tool) Version 5.98, part of FSL (FMRIB's Software Library; Smith et al., 2004). The following pre-statistics processing was applied: motion correction (MCFLIRT, Jenkinson et al., 2002), non-brain tissue removal, spatial smoothing using a 6 mm full-width at half-maximum Gaussian kernel, grand-mean intensity normalization of the entire 4D dataset by a single multiplicative factor. None of the participants exhibited motion that was greater than 3 mm (translation) and 1° (rotation), and the average frame-wise displacement was below 0.3. We

used MELODIC 3.0 as a part of FSL package to decompose each single subject 4D dataset into different spatial and temporal components using Independent Component Analysis (ICA). ICA components were manually classified as ones representing data artifacts from head motion, cerebrospinal fluid, white matter, and cyclic cardiac and respiratory noise, which were subsequently removed from the 4D dataset (cf., Salimi-Khorshidi et al., 2014). The cleaned data were then filtered using a high-pass temporal filter of 0.025 Hz. The filter cut-off was determined by the window length of 39.2 s (i.e., 20 volumes), which was used in the sliding-window analysis (see below), because the transient fluctuations of functional connectivity are limited to the cut-off frequency of the window length (Leonardi and Van De Ville, 2015). We carried out registration of the single subject 4D data to the high-resolution T1-weighted image, and the T1 to the 2 mm isotropic MNI-152 standard space image (T1 standard brain averaged over 152 subjects; Montreal Neurological Institute, Montréal, QC, Canada). The resulting transformation matrices were then combined to obtain a native to MNI space transformation matrix and its inverse (MNI to native space).

Physiological data acquisition and preprocessing

Skin conductance was recorded during the fMRI acquisition using Ag/AgCl electrodes attached to the palmar surface of the left index and middle finger, and the signal was amplified and digitalized via a skin conductance processing unit (Nexus-16, Mind Media). The signal was recorded digitally at the sampling rate of 100 Hz using Biotrace software (Mind Media), and then resampled to 32 Hz. We preprocessed skin conductance level (SCL) time series with a low-pass filter of 2 Hz, which is a standard procedure (Boucsein et al., 2012).

Sliding-window functional connectivity and statistical analyses

Seeds of the left and right amygdala were created with the Harvard-Oxford Subcortical Structural Probability Atlas (80% probability) provided by FSL (Fig. S1a). The left and right amygdala were used separately, because lateralization effects have been reported in the fear conditioning literature (Baker and Kim, 2004; van Well et al., 2012), and have been found in the original report of the study as well (Bilkei-Gorzo et al., 2012). To assess time-varying FC, the fMRI datasets and amygdala time series were partitioned into rectangular windows with a length of 39.2 s (i.e., 20 volumes), well within range of a window length between 30–60 s, which has been considered feasible previously (Jones et al., 2012). The windows were shifted by one volume at a time (98% overlap between adjacent windows). Next, amygdala FC was determined for each window by regressing (using the GLM, as implemented in the FSL tool “fsl_glm”) the amygdala time series against the time series of all other voxels. FC maps of all windows were then concatenated in the temporal domain to create a single 4D connectivity data set.

Four steps were undertaken to evaluate whether sliding-window analysis can reveal functionally relevant amygdala connectivity dynamics during the fear conditioning paradigm. First, to evaluate the functional relevance of patterns of amygdala FC change over time, simultaneously acquired skin conductance level (SCL) time series were resampled to match the TR of the fMRI data, and subsequently averaged over time frames that corresponded to the windowed time series of amygdala FC. Associations between fluctuations in SCL and amygdala sliding-window FC were assessed using the GLM, and finally tested across the group using non-parametric statistics, as implemented in the FSL tool “randomise” (5000 permutations; Winkler et al., 2014). To avoid an arbitrarily selected cluster-size forming threshold, and to enhance areas of signal that exhibit some spatial contiguity in the group-level statistical map, we used the threshold-free cluster enhancement (TFCE) algorithm, and subsequently corrected the results for multiple comparisons at $p < .05$ by using the null distribution

of the maximum TFCE value across the map (Smith and Nichols, 2009). In the group-level analysis, we used a mask of the minimum whole brain coverage across all participants (Fig. S2).

Second, to provide evidence for non-stationarity of the connectivity results obtained with the sliding-window analysis and its association with SCL, we performed additional analyses with surrogate data (cf. Hindriks et al., 2015). To obtain surrogate time series, we used the Amplitude Adjusted Fourier Transformed (AAFT) algorithm implemented in MATLAB as an open-source function (Barnett, 2016), which preserves the amplitude, mean, variance, and the amount of auto-correlation of the original time series (Kugiumtzis, 2000). We restricted this analysis to connectivity between the amygdala and a spherical region of interest (ROI) of 6mm radius centered around the peak significant voxel (resulting from the first analysis) in the anterior cingulate cortex (ACC; MNI coordinates: 4, 32, 18; see Fig. S1b). The BOLD time series from the left amygdala seed and this ACC ROI were extracted for each individual. Then we generated 1000 AAFT surrogate BOLD time series of the left amygdala and ACC ROI, and computed sliding-window FC between them. Subsequently, to test whether the variability of the sliding-window FC (left amygdala-ACC ROI) is higher than could be expected by chance, the standard deviation of the obtained sliding-window connectivity time series was computed per iteration. As a result, a null distribution of group averaged standard deviation values was obtained (Fig. S3a), and used to test whether the group averaged standard deviation of the true left amygdala-ROI sliding-window time series is a random draw from the null distribution. Additionally, to test whether the association between amygdala sliding-window FC with SCL was merely found by chance, sliding-window connectivity time series between the left amygdala and the ACC ROI were extracted for each individual, and then fed into the AAFT algorithm to generate 1000 surrogate time series of sliding-window FC. The surrogate time series were subsequently used in the GLM with the true individual SCL time series as a predictor. A group averaged t value was computed per iteration. As a result, a null distribution of group averaged t values expressing the temporal association between the SCL time series and surrogate sliding-window FC was obtained (Fig. S3b). We then tested the null hypothesis that the true observed group averaged t value would be a random draw from this null distribution.

Third, we assessed the spatial specificity of the sliding-window amygdala connectivity. Initially, to explore whether sliding-window amygdala connectivity deviates spatially from its typical static representation (cf. Betzel et al., 2016), we performed a standard whole-brain seed-based connectivity analysis across the whole task scan for the left amygdala. A voxel-wise FWE threshold of $p < .05$ was used to identify a spatial pattern of FC across participants, which exhibits the strongest temporal association of the amygdala. Note that TFCE-based correction was not used for this analysis, as the input images (individual amygdala connectivity maps) mostly contained positive values. In this case, TFCE fails to produce informative results, as it will produce significance across the whole brain. Subsequently, to determine whether the observed pattern of fluctuations in FC is specific for the amygdala rather than due to unlocalized global activity (Scholvinck et al., 2010), we performed additional analysis for a control region. Specifically, to better disentangle the effects of global vs. induced arousal measured with SCL, we chose a region that has a high signal-to-noise ratio (SNR), and should be activated by the task. The primary visual cortex fulfilled both these criteria, as it typically shows a high SNR and should be activated by the presentation of visual stimuli in the task, which were sometimes paired with the electric shock. The mask for the seed in the visual cortex was derived from a template of the primary visual cortex by Shirer et al. (2012). The template (Functional Imaging in Neuropsychiatric Disorders [F.I.N.D.] Lab, 2016) was eroded by a kernel of 4 mm-radius-sphere, yielding our seed mask of the primary visual cortex seed (Fig. S1c).

Fourth, to further test whether the temporal association between

the amygdala FC changes and SCL obtained with the sliding-window analysis are of functional relevance, we performed a PPI analysis, which is the conventional method to study connectivity changes over time when changes in physiology (or task conditions) are known (Friston et al., 1997; Prado and Weissman, 2011). Although we did not model task predictors in our analysis, SCL can be used as an indirect model of task-related response, and hence be used as a predictor for FC changes in the PPI analysis. If its results were to be comparable with the results of the sliding-window analysis, this would increase confidence that the sliding window approach is able to capture FC dynamics in the context of our task. To this end, we resampled the preprocessed SCL time series to the total number of volumes in the scanning session (i.e., 413). The skin conductance impulse response function resembles the canonical hemodynamic response function very closely in its shape and latency (Bach et al., 2009; Lim et al., 1997), so that SCL could be cross-correlated with BOLD signal without additional processing (i.e., without convolution with a hemodynamic response function). The GLM was conducted with regressors for: (1) the main effect of the seed regressor, (2) the main effect of the SCL time series regressor, and (3) the interaction of the seed (demeaned) and SCL regressor (centered), which was treated here as the regressor of interest, and which was used in the second level random effects analysis performed with the same non-parametric statistics as used for the sliding window analysis (5000 permutations; $p < .05$, TFCE corrected for multiple comparisons).

Lastly, we assessed the association between fluctuations in BOLD activity and SCL across the whole task scan to compare the results of sliding-window connectivity with mere fluctuations in BOLD. To this end, we used SCL, resampled to the number of TRs, as a predictor in the GLM, and examined both its positive and negative associations for each participant separately. The resulting individual statistical maps were then subjected to a second level random effects analysis with the same parameters as were used above (5000 permutations; $p < .05$, TFCE corrected for multiple comparisons).

Voxelwise uncorrected (t) and corrected (TFCE p) statistical maps, as well as seed maps of all analyses are available on NeuroVault.org (Gorgolewski et al., 2015) via this link: <http://neurovault.org/collections/2274>.

Results

Fluctuations in skin conductance level and presentation of electric shocks

Standard analysis of skin conductance response, time-locked to the presentation of electric shocks, was previously reported in the original study. To indicate the most representative time course across the group of participants, we ran a principal component analysis (PCA) on the set of individual SCL time series. Fig. 1a depicts the first eigen-time-series of SCL across the entire task scan, in which the red vertical lines indicate the timing of electric shocks. SCL typically rises after the shock and tends to recover in between consecutive shocks. Taken together, these results indicate that the fear conditioning task, and especially the presentation of shocks, affected the fluctuations of SCL.

Sliding-window analysis of amygdala FC and SCL

To investigate the temporal relationship between amygdala FC and fluctuations in SCL during fear conditioning, we employed a whole brain seed-based sliding-window FC analysis with 98% overlap between two consecutive windows (i.e., shifting the window by one volume at a time). The fluctuations in SCL significantly co-varied with the fluctuations in left amygdala FC obtained with the sliding-window analysis. We identified a set of regions comprising the bilateral insula and anterior cingulate cortex (ACC), reminiscent of the salience network (Seeley et al., 2007), which became more strongly coupled with

Fig. 1. First eigen-time-series of skin conductance level and amygdala-ACC sliding-window connectivity across participants. The time courses of the first eigen-time-series of (A) skin conductance level across the entire task scan, and (B) left amygdala-ACC sliding-window connectivity, which are most representative across the group of participants. The red vertical lines indicate the timing of electric shocks, for 1a in TRs, for 1b in windows, where shocks are depicted at the window numbers in which shocks occurred exactly at the middle TR of the window.

Fig. 2. Temporal association between fluctuations in functional connectivity and skin conductance level. The statistical maps represent regions for which temporal fluctuations in functional connectivity of the left amygdala (panel A) and primary visual cortex (panel B), as obtained with the sliding-window analysis, show a positive association with fluctuations in skin conductance level. The voxelwise TFCE map is significant at $p < .05$, corrected for multiple comparisons, and overlaid on the 2 mm MNI template in radiological convention. Numbers in the bottom row indicate coordinates of the sagittal, coronal, and axial sections in MNI standard space.

the left amygdala during periods of increased SCL (Fig. 2a; Table 1). We did not find any significant result for the right amygdala at the corrected threshold of $p = .05$. Even the uncorrected map, liberally thresholded at $p = .01$ did not show the clear pattern of the right amygdala. No negative associations were observed for the left or right amygdala.

To explore the most representative pattern of fluctuations in sliding-window connectivity across the group of participants, we performed a PCA on the individual sliding window connectivity time series between the amygdala and the ACC ROI that showed the strongest effect. Fig. 1b depicts the first eigen-time-series of the sliding-window connectivity, with vertical red lines (roughly) indicating the time points of electric shocks. Overall, there seems to be good correspondence between exposure to shocks and increases in the amygdala-ACC sliding-window connectivity.

Assessment of non-stationarity

To determine non-stationarity of the connectivity time series obtained with the sliding-window analysis, we calculated 1000 surrogate BOLD time series for the left amygdala and ACC ROI (cf. Hindriks et al., 2015). Per iteration, the standard deviation of the time-varying connectivity between the two surrogate time series was computed. As a result, a null distribution of group averaged standard deviation values was obtained (Fig. S3a), and used to test whether the group averaged standard deviation of the true left amygdala-ROI sliding-window time series could be a random draw from the null distribution. The true observed group averaged value of the standard deviation was 0.265, and its probability under the null distribution was $p = .024$. This result suggests that the variability of the sliding-window FC during our task is unlikely to have emerged simply by chance, and could thus be considered non-stationary.

Secondly, to test the validity of the association between amygdala

Table 1
Regions that show a positive association between sliding-window functional connectivity of the left amygdala and fluctuations in skin conductance level.

Region	L/R	Number of voxels	Peak coordinates (MNI)			p-value
			x	y	z	
Anterior Cingulate Gyrus	R	4016	6	22	18	.001
Inferior Frontal Gyrus/Pars Opercularis	R	510	56	10	2	.004
Cingulate Gyrus	L	291	−2	−4	38	.025
Superior Frontal Gyrus	R	56	22	46	24	.042
Brainstem	L	50	−4	−14	−10	.017
Supplementary Motor Cortex	L	33	−6	14	54	.045
Inferior Frontal Gyrus	R	18	44	28	4	.037
Orbitofrontal Cortex	R	16	24	30	−14	.033
Thalamus	R	15	16	−10	14	.039
Brainstem	R	11	12	−8	−12	.037
Postcentral Gyrus	L	3	−50	−10	22	.048
Thalamus	L	1	−4	−22	−2	.048

Clusters are significant at $p < .05$, TFCE corrected for multiple comparisons. Anatomical labels of the peak voxel coordinates are identified with the Harvard-Oxford (Sub-) Cortical Structural Probability Atlas. R: right hemisphere; L: left hemisphere.

sliding-window FC with SCL, we generated a null distribution of group averaged t values expressing the temporal association between the true SCL time series and a 1000 surrogate sliding-window FC time series (Fig. S3b). We tested the null hypothesis that the true observed group averaged t value could be a random draw from this null distribution. The true observed value was $t=3.74$, and its probability under the null distribution is $p < .001$. This result suggest that the temporal association between the fluctuations in left amygdala FC and SCL, as obtained with the sliding-window analysis, is in fact dependent on the sequence of events in time, rather than reflecting general low frequency fluctuations that are unspecific to the task.

Spatial specificity of the sliding-window amygdala results

The pattern of static amygdala connectivity is in line with what was reported previously (e.g., Veer et al., 2011; Roy et al., 2009), although

only positive connectivity values were found here, while it was qualitatively different from the pattern that emerged from the sliding-window analysis (see the Fig. S4). This suggests that the sliding-window connectivity of the amygdala associated with SCL is spatially distinct from the static (averaged) FC of the amygdala.

Next, we examined whether we could observe similar associations between SCL and time-varying FC for the primary visual cortex, an area that was not expected to mediate the effects of fear conditioning present in changes of SCL. We found several regions that exhibited a positive association between the fluctuations in primary visual cortex sliding-window connectivity and SCL. In comparison to the results of the sliding-window analysis of the left amygdala, FC of the primary visual cortex seemed to increase with a more dorsal part of the left mPFC, the superior PFC, and the caudate during periods of elevated SCL (Fig. 2b). However, a formal statistical test only demonstrated this differentiation at a lenient uncorrected threshold ($p < .05$).

Physio-physiological analysis

To test whether the results obtained with the sliding-window analysis are comparable to a more standard method to test for connectivity changes as a function of SCL, we performed a PPI analysis. Again, we restricted our analysis to the left amygdala. We found only one cluster that showed significant results (right anterior insula: peak coordinates MNI=46, 14, −12; $p=.036$; cluster size=24 voxels). However, at a liberal uncorrected threshold ($p < .01$) the PPI analysis demonstrated a connectivity pattern similar to the sliding-window analysis (Fig. 3). This finding does not only suggest that sliding-window analysis may be a feasible method to capture transient and functionally relevant changes in FC during a task, but also suggests that it may even be more sensitive than the commonly used PPI analysis to reveal time-varying connectivity.

Association between SCL and fluctuations in BOLD activity across the whole task scan

We did not observe any significant results for the positive contrast at a whole-brain corrected threshold. However, only at the very lenient uncorrected threshold of $p=.05$ we found clusters in the bilateral anterior insula. The negative contrast did show an association with visual and sensorimotor regions that survived correction for multiple comparisons and is depicted in Fig. S5. These findings suggest that SCL

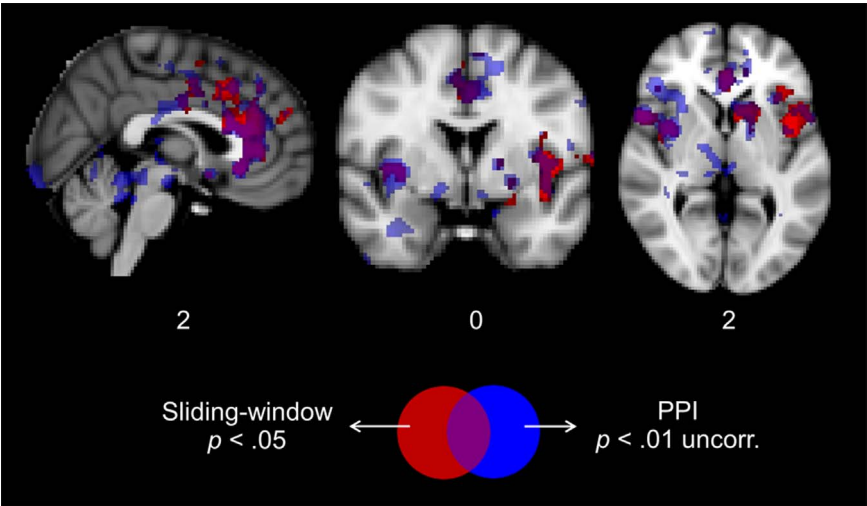

Fig. 3. Temporal association between fluctuations in functional connectivity and skin conductance level using sliding-window and physio-physiological interaction (PPI) analyses. The statistical maps represent regions for which temporal fluctuations in functional connectivity of the left amygdala show a positive association with fluctuations in skin conductance level, as obtained with either the sliding-window or PPI analysis. The voxelwise TFCE maps are reported for corrected ($p < .05$) and uncorrected ($p < .01$) thresholds for the sliding window and PPI analysis, respectively, and were overlaid on the 2 mm MNI template in radiological convention. Numbers in the bottom row indicate coordinates of the sagittal, coronal, and axial sections in MNI standard space.

alone is associated with a qualitatively different pattern of brain activation than its relation with amygdala sliding-window functional connectivity.

Discussion

In the present study we set out to test whether sliding-window analysis could reveal behaviorally relevant time-varying connectivity fluctuations. To this end, sliding-window amygdala functional connectivity (FC) was assessed during a well-established fear conditioning paradigm, and was linked to changes in physiological arousal and vigilance, as reflected by changes in skin conductance level (SCL). During periods of increased SCL, the left amygdala became more strongly coupled with the bilateral insula and medial prefrontal cortex, most notably the anterior cingulate cortex (ACC). This result was unlikely to have emerged merely by chance, as it was not present in the surrogate data. Moreover, it was spatially distinct from the static left amygdala FC and from sliding-window FC of a control seed in the visual cortex. FC of the right amygdala did not exhibit fluctuations associated with changes in SCL. Furthermore, the more commonly used physio-physiological interaction (PPI) analysis demonstrated a connectivity pattern of the left amygdala that was similar to the sliding-window analysis, albeit only at a liberal uncorrected threshold.

With the sliding-window analysis we identified a specific connectivity pattern that is associated with gradual changes in SCL, and is spatially distinct from its static (averaged) connectivity (Roy et al., 2009; Veer et al., 2011). Skin conductance is typically used to quantify both tonic and phasic arousal (Boucsein, 2012; van Olst et al., 1967). In the current study, we mostly captured the tonic component, on top of which phasic changes occurred that were elicited by the stimulus presentations. Previously, such changes were associated with vigilance performance in attention demanding tasks (Blakeslee, 1979; Frith and Allen, 1983), and with the level of arousal elicited by either positive or negative pictures (Bradley et al., 2001). Hence, we attribute the changes in SCL to changes in physiological arousal and vigilance induced by the presentation of shocks.

SCL was associated with a qualitatively different pattern of fluctuations in BOLD activity across the whole task scan than its association with amygdala sliding-window FC, which comprised regions of the salience network (Seeley et al., 2007). This network is typically associated with the detection of behaviorally salient events and has been implicated in dynamic switching between the DMN and the central executive network (Chen et al., 2013; Goulden et al., 2014; Jilka et al., 2014), which can be tracked by a physiological index of arousal (i.e., heart rate; Young et al., 2016). The salience network was found to be activated during fear conditioning tasks (Sehlmeyer et al., 2009) and pain perception (Garcia-Larrea and Peyron, 2013). Notably, the ACC and parts of the bilateral insula seemed strongly coupled with the left amygdala during the periods of increased SCL. This in contrast to the connectivity profile of the primary visual cortex, which connectivity changes were likely induced by the presentation of visual stimuli in the experiment. These results suggest that the sliding-window method captured time-varying FC of the left amygdala related to distinct cognitive processing involved in the acquisition of a fear response. Specifically, FC between the amygdala and insula seems to be associated with regulating vigilance (Denny et al., 2014; Stein et al., 2007a, 2007b), whereas FC between the amygdala and medial PFC is typically involved in the regulation of autonomic states, such as skin conductance and cardio-vascular activity (Etkin et al., 2011; Gianaros et al., 2008; Wager et al., 2009). Ongoing cardio-vascular parasympathetic activity was previously associated with the fluctuations in the strength of the amygdala-mPFC coupling while individuals were watching sadness-inducing film excerpts (Raz et al., 2012). Therefore, we infer that the observed connectivity changes were likely driven by the task, which influenced amygdala-insula FC due to an increased, but unknown probability of receiving an electric shock

(vigilance), as well as amygdala-mPFC coupling due to the presentation of the shock itself (autonomic regulation). This was corroborated by the seemingly good overlap between shock exposure and increases in both SCL and amygdala sliding-window connectivity. In contrast, we did not find the effect in the right amygdala, despite its well-established involvement in fear extinction (LaBar et al., 1998), pain (Ji and Neugebauer, 2009), and processing of negative emotions (Angrilli et al., 1996).

Previous studies used simulated data to evaluate the performance of the method, and provided guidelines for the choice of its parameters, and for how to carry out hypothesis testing. Following these guidelines, we evaluated the performance of sliding-window analysis in empirically acquired task data, for which the neural correlates have been well-described before. We found that sliding-window analysis was able to detect variation in FC over time associated with changes in SCL, which were (in part) evoked by the fear conditioning paradigm. Importantly, these changes were significantly different from those obtained with surrogate data. In a previous study, however, sliding-window derived fluctuations in FC across time that was based on randomly shuffled data resembled the variability of non-shuffled data quite well (Hindriks et al., 2015), which questioned the validity of the method in revealing true connectivity dynamics. Although a direct comparison between their and our findings is hampered by the different nature of the data (resting-state vs. task-based conditions), similarly to Hindriks and colleagues we emphasize that a statistical description of sliding-window fluctuations alone is not sufficient to reveal its functional relevance, but only becomes informative when supported by associations with a concurrent behavioral or physiological measure. To give meaningful interpretation of potentially insignificant connectivity fluctuations in our study, we used simultaneously acquired SCL, which enabled us to validate the time course of such connectivity fluctuations against another task-derived measure. Therefore, for future studies we would like to stress the importance of collecting a behavioral (and/or physiological) measure, which could be used as a temporal model, and thus as an external validation, for studying gradual network dynamics associated with changes in cognition.

Lastly, we demonstrated that traditional PPI analysis was able to reveal a similar pattern of time-varying connectivity as the sliding-window analysis albeit only at a liberal uncorrected threshold, which provides convergent validity for our findings. Moreover, it seemed that more robust results were generated by the sliding-window analysis. We propose a twofold interpretation of these results: (i) sliding-window FC did show a cognitively-relevant pattern of fluctuations that is typically captured by PPI analysis on task-based fMRI data; (ii) sliding-window analysis may ultimately generate more sensitive results, as it captures the overall effect of the task, whereas PPI analysis isolates the effects of the seed, the task (i.e., the SCL in the current analysis), and the interaction, which might lack efficiency when one of the two main regressors is correlated with the interaction term (Friston et al., 1997). Yet, the potential higher sensitivity of the sliding-window compared to PPI should be investigated in a range of task contexts, including the test-retest reliability of the two methods. This would give more confidence about whether the sliding-window method truly can be deemed more robust, and could exclude the alternative possibility that the lower *p* values obtained with the PPI analysis may speak for its selectivity rather than for less sensitivity.

Limitations and possible improvements

We used SCL as a non-vascular index of autonomic activity that should be less intertwined with BOLD than cardiovascular measures, such as heart rate variability (e.g., Chang et al., 2013b). Yet, both SCL and cardiovascular measures are important markers of autonomic nervous system activity, and hence are not easy to treat as independent measures. Indeed, it is likely that changes in SCL are accompanied by changes in cardiovascular measures and/or respiration. Unfortunately,

none of these additional autonomic indices (ECG/pulse oximeter, respiration) were acquired, thus we could not test to what extent SCL is collinear with these types of data.

In this study we did not only take advantage of employing simultaneously acquired SCL as a temporal model of connectivity changes, but also of incorporating task conditions. While the task paradigm enabled us to infer whether the observed connectivity changes associated with SCL reflect cognitive processing, in this case threat appraisal, one must acknowledge that transient co-activation in response to external stimulation can be interpreted as functional connectivity, even when no information exchange might exist. Nevertheless, we believe that the dynamics we observed between the amygdala and regions of the salience network do reflect meaningful “cross-talk” between these regions. The existing literature shows consistent involvement of the amygdala and the salience network in fear conditioning, which orchestrated activity creates a state of readiness to respond to potential threat (Fullana et al., 2016; Phelps et al., 2001). In addition, it is more likely that transient and consistent task induced co-activation truly reflects information exchange if the regions involved are anatomically connected as well. Both primate and human studies show that the amygdala has a vast number of anatomical projections to the medial PFC and insula (Barbas and De Olmos, 1990; Amaral and Price, 1984; Ghashghaei and Barbas, 2002; Kim et al., 2011; Fani et al., 2015; Greening and Mitchell, 2015), which enables the functional integration that contributes to fear processing and regulation (Stein et al., 2007a, 2007b; Liu et al., 2011; Wheelock et al., 2014; Vytal et al., 2014). Also, persistent activity of the network was observed in the aftermath of the fear conditioning, which further suggests its involvement during the acquisition of fear (Feng et al., 2014). Lastly, if the synchronization between the amygdala and the salience network was only due to external stimulation, it should be present among all regions involved in the task. While the seed in the visual cortex was involved in the task and its activity coincided with the task stimulation, it showed a qualitatively different spatial pattern of connectivity changes with SCL. This further corroborates our interpretation of information exchange between the amygdala and the salience network, instead of having found mere co-activation.

The task paradigm might have induced substantial variation in connectivity fluctuations over time (Garrett et al., 2013), which differs significantly from fluctuations observed during resting-state. Such a possibility hampers the generalizability of our findings to resting-state conditions. However, recently Betzel et al. (2016) showed that during resting-state there is a number of periods during which manifest in- or decreases in connectivity are present, which in turn, influence the modular topology of resting-state networks. In addition, the topography of resting-state networks not only can be obtained by temporal correlation of fMRI signals, but also by extracting brief moments when the regions are transiently co-activated (Tagliazucchi et al., 2016; Liu and Duyn, 2013). It is therefore possible that task-induced co-activations persist in the subsequent resting-state period (Allan et al., 2015), during which the dynamics of the amygdala connectivity observed in the current study might be present as well. Future studies should directly investigate the relationship between connectivity changes during resting and task conditions to better characterize temporal models of fluctuations in cognition and behavior over time.

Sliding-window analysis typically suffers from a relatively small number of data points (for a common TR of 2 s), which might be overcome with recent technological advances in fMRI acquisition. For example, multiband imaging (Feinberg et al., 2010; Moeller et al., 2010) allow sub-second repetition times, and thereby provide an increase the number of sample points. This, in turn, increases the robustness of the correlation estimates, and enables better characterization of high-frequency components, which are mostly affected by non-neuronal noise such as cardiac and breathing rhythms. In addition to physiological noise, fMRI time-varying FC might be affected by variations in the BOLD signal mean and variance over time, hardware

instability, or residual head motion. Though effects of the latter are highly debated in the functional connectivity community, a recent study demonstrated the existence of transient FC patterns in anesthetized monkeys (Hutchison et al., 2013b). Nevertheless, BOLD fluctuations are dominated by low frequencies, which makes fMRI particularly challenging to study connectivity dynamics. Yet, spectral characteristics of BOLD activity reveal that resting-state networks are in fact broadband processes that span a wide frequency spectrum (Niazy et al., 2011), but are temporally blurred by the hemodynamic response function. Recently developed signal processing techniques, which are able to temporally deconvolve fMRI time series, may prove helpful to use the full-spectrum of fMRI signal, and hence provide better estimates of fMRI connectivity dynamics (e.g., Karahanoglu and Van De Ville, 2015).

Given that BOLD is an indirect measure of neuronal activity, it remains challenging to elucidate whether fMRI time-varying FC represents dynamics of neuronal activity between distant brain regions. Neuronal dynamics mostly have been investigated using electrophysiological recordings of single cells, local field potentials, and surface EEG (for a review, see Rabinovich et al., 2012). Oscillations of electrical activity observed at different frequencies enable populations of neurons to synchronize their activity over various time scales (Friston and Buzsaki, 2016; Kiebel et al., 2008; Varela et al., 2001). Simultaneous EEG-fMRI studies have shown that BOLD connectivity variability partly reflects changes in neuronal synchrony associated with changes in vigilance states (Chang et al., 2013a; Scheeringa et al., 2012; Tagliazucchi et al., 2012). Hence, dynamics of BOLD connectivity may emerge through transient synchrony in electrophysiological signals at multiple time scales. We can only speculate that the fMRI connectivity fluctuations identified with SCL time series indeed stem from underlying neuronal dynamics. Future studies of simultaneous EEG-fMRI with a concurrently measured behavioral or physiological variable should shed more light on the neuronal sources of fMRI time-varying FC.

Conclusions

Using sliding-window analysis, we demonstrated that fluctuations in left amygdala FC with regions of the salience network were associated with transient changes in physiological arousal and vigilance. These, in turn, were likely induced by a repetitive exposure to unconditioned aversive stimuli (shocks) in our fear conditioning paradigm. The results of the sliding-window analysis were demonstrated to be unlikely to have occurred by chance, were spatially distinct from static amygdala FC and from sliding-window FC of a control seed, but were highly comparable to the results of the PPI analysis. We conclude that sliding-window analysis can reveal functionally relevant connectivity fluctuations in the context of an externally cued task.
